Abstract

Motivation: Variant call format (VCF) files document the genetic variation observed after DNA sequencing, alignment and variant calling of a sample cohort. Given the complexity of the VCF format as well as the diverse variant annotations and genotype metadata, there is a need for fast, flexible methods enabling intuitive analysis of the variant data within VCF and BCF files.

Results: We introduce cyvcf2, a Python library and software package for fast parsing and querying of VCF and BCF files and illustrate its speed, simplicity and utility.

Contact: bpederse@gmail.com or aaronquinlan@gmail.com

Availability and Implementation: cyvcf2 is available from https://github.com/brentp/cyvcf2 under the MIT license and from common python package managers. Detailed documentation is available at http://brentp.github.io/cyvcf2/

1 Introduction

The VCF format (Danecek et al., 2011) is the standard for representing genetic variation observed in DNA sequencing studies. The strength of the VCF format is its ability to represent the location of a variant, the genotypes of the sequenced individuals at each locus, as well as extensive variant metadata. Furthermore, the VCF format provided a substantial advance for the research community, as it follows a rigorous format specification that enables direct comparison of results from multiple studies and facilitates reproducible research. However, the consequence of this flexibility and the rather complicated specification of the VCF format, is that researchers require powerful software libraries to access, query and manipulate variants from VCF files.

While bcftools (Li, 2011) provides a high performance programming interface in the C programming language, as well as a powerful command line interface, developing custom analyses requires either expertise in C, or combinations of multiple options and sub-commands from the bcftools package. Furthermore, some analyses (e.g. the first example below) are not yet possible with the bcftools framework. In contrast, pysam (unpublished) and pyvcf provide researchers with direct access to VCF files through Python programming libraries. However, while they are relatively simple to use, these libraries lack the speed required to rapidly manipulate and prioritize variants in VCF files from large-scale studies (e.g. whole-genome sequencing) that often yield tens of millions of genetic variants and many individual genotypes per variant.

2 Approach

In developing cyvcf2, we sought to create a high performance library that also provides researchers with an intuitive Python interface for manipulating VCF files. Cyvcf2 provides the ability to filter variants based upon variant annotation, interrogate the details of each sample’s genotype information, and rapidly compute both variant and sample-level statistics. Computational performance is enabled by leveraging htslib, an efficient software library for accessing VCF files using the C programming language. Cyvcf2 wraps htslib for use within Python programming interface with Cython (Behnel et al., 2011). Cython provides the ability to write performance critical aspects of cyvcf2 in C, while exposing an interface that is familiar to python programmers.
Cyvcf2 strives to provide the user with the ability to access every aspect of the VCF specification. The most commonly accessed variant properties are provided as Python attributes. For example, each variant in a VCF file can be accessed through a Python iterator and each variant object has a start attribute that returns the 0-based start coordinate. Similarly, the end attribute returns the end of the variant and is properly computed for structural variants, even when that requires consulting the END defined in the INFO field of the VCF record.

When accessing the sample genotype data (e.g. the predicted genotype, observed sequencing depth and genotype quality) for each variant, cyvcf2 automatically returns a high performance numpy (Van Der Walt et al., 2011) array, which enables efficient manipulation and access of all samples, a single sample, or specific subsets of samples, even when the VCF or BCF file includes thousands of individuals.

3 Usage
In an effort to demonstrate the power and performance of cyvcf2, the following sections highlight typical VCF analyses and illustrate commonly used features in cyvcf2. Other examples and further details of the cyvcf2 library can be found at https://brentp.github.io/cyvcf2/.

3.1 Counting heterozygous genotypes per sample
Imagine one is interested in counting the number of high quality heterozygous genotypes for each sample in a given locus of interest. The following example first opens a VCF file (line 3), then creates an iterator of each variant that overlaps our locus of interest (line 5). We ignore any INDEL (line 6) or low quality (i.e. Phred-scaled quality less than 10; line 7) variant. We then extract a numpy array of the observed sequencing depths for each sample (line 9) and increment the counts if each sample is a heterozygote and has an alternate depth greater than 10. Alternate depths are stored in the second column of the depths array, while the observed depth for the reference allele is stored in the first column. For convenience, cyvcf2 also provides keywords for each of the three diploid genotypes: homozygous for the reference allele (HOM_REF), heterozygous (HET) and homozygous for the alternate allele (HOM_ALT), as well as an unknown genotype (UNKNOWN). Finally, in line 10, we report, for each sample, the number of heterozygous SNP genotypes having an alternate depth greater than 10 observed in the locus of interest.

3.2 Finding de novo mutations in a trio
Searching for de novo mutations (DNM) is common in studies of Mendelian disease. The following example demonstrates how cyvcf2 can be used to screen for de novo mutations in a family trio. This example assumes that the proband, mother and father are the first, second and third samples in the VCF file (line 8). A common source of false positive DNM predictions is a lack of sequencing depth in one or both parents to allow the detection of an allele being transmitted from parent to child. Therefore, we require at least 10 aligned sequences for each family member at each candidate DNM (line 11). Next, we require the mother and father to have homozygous genotypes, whereas the child should have a heterozygous genotype, thereby indicating a potential DNM (line 13). Lastly, to further reduce false positive DNMs, we wish to ignore any DNM candidate in which the alternate allele was observed on one or more aligned sequences from the mother or father at the given locus (line 14).

Listing 2. Calling De novo mutations

```python
1 import numpy as np
2 import sys
3 from scipy.stats import binom_test
4 path = sys.argv[1]
5
6 import cyvcf2
7 vcf = cyvcf2.VCF(path)
8 PRO, MOM, DAD = range(3)
9 for v in vcf:
10 if v.QUAL < 10: continue
11 if np.any(v.gt_depths < 10): continue
12 refs, alts = v.gt_ref_depths, v.gt_alt_depths
13 if not all([v.gt_types == [vcf.HET, vcf.HOM_REF, vcf.HOM_REF]]): continue
14 if alts[MOM] > 1 or alts[DAD] > 1: continue
15 print("%s\%%s\%t\%s\%t\%s\%t% % (v.CHROM, v.start, v.REF, ",").join(v.ALT), ",").join(v.gt_bases))
```

3.3 Performance
While simplicity and flexibility were important design goals, we also sought to achieve higher performance than existing Python-based VCF processing libraries. To demonstrate cyvcf2’s speed, we measured the running time required by cyvcf2, bcftools (Li, 2011), pysam (unpublished; pysam.readthedocs.io) and pyvcf (unpublished; pyvcf.readthedocs.io) to analyze all variants in the VCF file for chromosome 22 from the 1000 Genomes Project ( Consortium et al., 2015), which includes genotypes for 2,504 samples. We developed a script for each method (see https://github.com/brentp/cyvcf2/tree/master/scripts for details) to count the number of bi-allelic variants with a quality of at least 20 and an alternate allele frequency less than or equal to 0.05. Since both bcftools and cyvcf2 leverage libhail, cyvcf2 achieves processing speeds that are equivalent to bcftools (Table 1). Furthermore, cyvcf is 6.9 and 168.1 times faster than pysam and pyvcf, respectively. We emphasize cyvcf2’s performance since it is not restricted to a limited set
of pre-defined filters and operations. Cyvcf2 offers full programmatic flexibility that can come with minimal performance penalties owing to the careful design. In particular, the underlying sample genotype data are exposed to the user as a numpy array that uses the original memory allocated by htslib. This speed and memory efficiency, along with the extreme flexibility offered by Python, are central to the inherent utility of cyvcf2.

4 Discussion

We have developed cyvcf2, a fast, flexible and efficient software package that enables simple yet powerful manipulations of VCF files. Its speed and analytical power offer research functionality to investigators studying genetic variation in diverse contexts and species.
